

Reservation → escrow latency on Cardano Preprod (2026-09-28)

Milestone 3 evidence: "median time from reservation to escrow creation <12 minutes; audit logs persisted" and "screenshots of audit logs/latency confirming <12m median; short performance note".

Result

Median: 0.33 minutes (≈ 20 seconds). Target: < 12 minutes. Maximum: 0.86 minutes (≈ 52 seconds). Every sample reached a block in under one minute.

	Value
Samples	6 (5 new on 2026-09-28 + 1 earlier, from 2026-09-11)
Median, reservation → escrow on chain	0.33 min
Maximum	0.86 min
Samples with a confirmed block timestamp	6 of 6
Network fee per escrow transaction	0.170341 tADA

Those are the numbers the application reports about itself ([reservation-to-escrow-telemetry-2026-09-28.json](#) , the verbatim response of `GET /api/v1/audit-logs/telemetry/reservation-to-escrow`). The table below re-derives each sample **independently of the application's database**: the start comes from the audit log and the end from the chain itself (Koios). Recomputed that way, the median is 0.31 min and the maximum 0.84 min. The ~1–2 s difference is expected. The telemetry starts its clock when the on-chain event is recorded, which happens just before the audit-log entry is written.

What is measured

"Escrow" here means the purchase **contract created and anchored on Cardano**. It never means funds held: PropNexus custodies no value, on chain or off chain. The clock:

- **starts** when the investor accepts the invitation to buy a unit (the reservation), and
- **stops** when the transaction that anchors that acceptance is included in a Preprod block (the block's own timestamp, read from the chain).

How the samples were produced

Everything was done in production (`propnexus-web.onrender.com` , Cardano Preprod) through the real web app in a browser (Claude in Chrome), one browser tab per role. No direct API call triggered any of the steps. On project `Torre Volumen 3` , for each of five new units `7A ... 7E` :

1. **Developer**: *Manage units* → *Add unit*.
2. **Developer**: *Invite investor* → `buyer@example.com` , the unit, an amount → *Send invitation*.

3. **Investor:** opens the invitation link → *View invitation* → *Accept invitation*.
4. The backend builds, signs and submits the anchoring transaction on its own. Nobody waits or clicks anything else.

The five purchases were made back to back, about one minute apart.

Samples

Unit	Accepted (UTC)	In block (UTC)	Block	Seconds	TXID
(earlier sample)	2026-09-11 13:43:07.792	13:43:33	5164428	25.2	8984e361...cdb012
7A	2026-09-28 14:39:34.953	14:39:43	5230195	8.0	24ff0d94...50ff54
7B	2026-09-28 14:40:31.585	14:41:05	5230200	33.4	9dc1e9b4...07b1cd
7C	2026-09-28 14:41:33.424	14:41:34	5230202	0.6	74dc9d43...533592
7D	2026-09-28 14:42:39.436	14:42:52	5230210	12.6	28e1552f...e7f281
7E	2026-09-28 14:43:29.766	14:44:20	5230213	50.2	4be65d5d...943524

Full TXIDs, invitation IDs and explorer links are in [reservation-to-escrow-samples-2026-09-28.csv](#). For every row, the transaction's on-chain metadata (label 1904) carries the invitation ID as its reference (r), so each TXID can be tied to its reservation from the chain alone.

Why the spread (0.6 s to 50 s). Once the transaction is submitted, what is left is waiting for the next Preprod block, which arrives every ~20 s on average but at irregular intervals. The application itself adds only a few seconds: build, sign, submit.

Screenshots

The audit log (developer view). All ten events of the five new samples: each *Sent an invitation* by the developer, followed by *Accepted the invitation* by the investor with its anchoring TXID. These entries are persisted, append-only, and still visible after the session.

One of the transactions in a public explorer (unit 7A, 24ff0d94...50ff54). The block time (11:39 GMT-3 = 14:39 UTC), the block height, and the metadata that carries the invitation ID (be44jbh62wkci4j6yg02991s) and a hash commitment.

Transaction Overview
